Introduction

Allotropes of carbon often exhibit extreme material properties due to the strong covalent bonds between atoms. In particular, carbon nanotubes (CNTs) and graphitic materials (i.e., graphite and graphene flakes, stacks, and nanoribbons) have garnered much interest due to their strong anisotropy. For example, while they are axially stiff, they are laterally compliant. In turn, there have been many attempts to incorporate such nanostructures into existing thermal abatement technologies. Carbon nanotubes have been suspended in liquids to increase the overall effective thermal conductivity of the liquids [2,3], as well as grown in arrays to act as thermal interface materials (TIMs) [4–7]. In addition, graphite has been implemented to structurally reinforce metallic heat spreaders while simultaneously increasing effective thermal conductivity [8,9]. However, despite the fact that the intrinsic thermal conductivity of these allotropes can exceed several thousand W m⁻¹ K⁻¹, their incorporation into existing thermal abatement technologies does not always produce correspondingly impressive results.

An important concept to keep in mind when considering the effective phononic thermal conductivity of a nanostructured composite system is the phonon mean free path (MFP). The phonon MFP describes the average distance a phonon travels before it scatters. The number of scattering events phonons undergo as they travel through a medium is one of several factors that dictate thermal conductivity of the medium itself. A larger MFP leads to a higher thermal conductivity. To put this in context, the phonon MFP is on the order of 100 nm at room temperature in solids [10] but can vary over several orders of magnitude depending on the phonon frequency and the particular material in question [11]. In many nanocomposites, the interfaces between different materials, which act as additional scattering sites, are spaced at distances less than the phonon MFP. In turn, the presence of many closely spaced interfaces can reduce the effective phononic thermal conductivity of the composite system. Consequently, thermal conductivity is governed as much by the interfaces between the constituent materials as it is by the materials themselves. If we are to maximize the effective thermal conductivity of a nanostructured composite employing CNTs or graphitic materials, we must first better understand phonon transport across the interfaces within the composite. In the subsequent discussion, our primary focus will be on the interface between isotropic thin films and a graphite substrate.

The efficiency of phononic thermal transport across an interface is often described by thermal boundary conductance, hBD, in units of W m⁻² K⁻¹. Thermal boundary conductance is generally a function of two factors: (i) the vibrational (phononic) spectra of the materials comprising the interface [12] and (ii) the condition of the interface itself [13].

With regard to the first factor, it would then be reasonable to assume that hBD at a solid-graphite interface is affected by the combination of the reduced dimensionality and anisotropy of graphite [14], as well as the large vibrational mismatch between the film and graphite [12,15]. For example, this vibrational mismatch is clear when looking at the phonon dispersion or density of states curves of metals and graphite. The maximum vibrational frequencies in metals are typically less than 10 THz [16,17], whereas the maximum vibrational frequency in graphite is in excess of 45 THz [18]. This large vibrational mismatch opens up the possibility of inelastic phonon–phonon processes contributing to phonon thermal transport across solid-graphite interfaces [19,20].

With regard to the second factor, the interfacial chemistry between metal films and graphite will have a significant impact on
the reported value of $h_{BD}$. Metal-graphite interaction is often charac-
terized by poor adhesion if significant carbide formation is not present. The poor adhesion at the metal-carbon interface is likely due to the fact that the stiff sp² bonds within a monolayer of graphite (graphene) prohibit significant chemical bonding between carbon and contacting materials, with interactions between the two instead described by weak dispersion forces. This theory has been experimentally demonstrated for Al [21] and Ti [22] on graphite. Additionally, it is well known that the adhesion energy at metal-
graphite interfaces is fairly low (<500 mJ/m²) [23]. Weak disper-
sion forces are associated with low-frequency, low-energy vibra-
tional modes. It is easy, then, to imagine this poor bonding will lead to poor thermal conductance across a solid-graphite interface.

To demonstrate the effect of poor adhesion on phononic ther-
mal transport across interfaces, Prasher [24] developed the van der Waals acoustic mismatch model. In this presentation, it was shown that low adhesion energies produce a significant reduction in interfacial thermal conductance. For example, the model predicts an 80% reduction in interfacial conductance when reducing the adhesion energy from 500 mJ/m² to 100 mJ/m². Molecular dynamics simulations have also been implemented to demonstrate that the lack of bonding between carbon allotropes and contacting materials will result in poor interfacial thermal conductance. She-
notin et al. [25] demonstrated that CNTs in octane liquid exhibit small thermal conductance at the CNT-liquid interface associated with the weak coupling between the rigid tube and the soft liquid (a similar situation to that of CNTs or graphene flakes embedded in polymer-based TIMs). Hu et al. [26] calculated that a single covalent bond between a CNT and a contacting Si surface would increase the interfacial thermal conductance by 2 orders of magni-
tude. Huxttable et al. [27] experimentally quantified $h_{BD}$ at a CNT-
liquid interface = 12 MW m⁻² K⁻¹.

In the present work, we present extensions of the diffuse mismatch model (DMM) [28,29] which can be implemented for the prediction of $h_{BD}$ at solid-graphite interfaces. These models are improvements over the DMM presented by Swartz and Pohl [30], as they account for both the anisotropy of graphite, as well as the possibility of inelastic scattering processes contributing to interfa-
cial phononic thermal transport. However, these models do not take into account the bonding, or lack thereof, between metal films and graphite substrates. To experimentally assess the role of interfacial chemistry and bonding on thermal transport at metal-graphite interfaces, different surface preparations are used before thin Au films are deposited on graphite substrates. Thermal boundary conductance at these interfaces is measured via the trans-
sient thermoreflectance (TTR) technique from 78 to 400 K. The temperature-dependent data are compared to modeled predictions, and the deviations from the models are discussed.

2 Modeling Thermal Boundary Conductance

Two primary models have been most widely employed for pre-
dicting $h_{BD}$ at interfaces between different materials: the acoustic mismatch model (AMM) and the DMM. The AMM treats pho-
onns as waves propagating in a continuous medium and assumes these waves do not scatter at an interface between two different materials; rather, phonon transmission and reflection is controlled by the relative mismatch in acoustic impedance of the materials [31]. Due to this continuum analysis, the AMM works best at low temperatures where dominant phonon wavelengths are long and frequencies are low. The DMM, on the other hand, operates at the other extreme, assuming all phonons scatter at the interface and do so diffusely. That is, phonons lose memory of their incident polarization and direction after scattering at the interface [30]. As a result, the DMM holds for elevated temperatures relative to the AMM. Still, the overall accuracy of the DMM has more recently come into question as the model has been applied to a larger data set. Several studies [12,32] have shown that the agreement between the DMM and experimentally measured values of $h_{BD}$ can vary by up to an order of magnitude.

2.1 Derivation of the Diffuse Mismatch Model. The DMM has been derived in full several times in the literature [30,33–37]. However, due to the varying assumptions applied during these derivations, many subtleties of the model are confused or even lost altogether [36]. The derivation is outlined here to ensure that these subtleties are not overlooked and to make it possible to address the relative importance of these subtleties under the present set of assumptions. The phonon flux, $q$, across an interface from side 1 to side 2 can be represented as

$$q_{1 \rightarrow 2} = \frac{1}{(2\pi)^2} \sum_{j, k_j, k_z} \int_{k_{j1z1}}^{k_{j2z2}} \int_{k_{z1}}^{k_{z2}} h_{BD}(k_{j1}) v_{1}^{\text{inc}} \left| v_{1}(k_{j1}) \right| f_0(k_{j1}) d\mathbf{k}_{j1} d\mathbf{k}_{z1}$$

where $z$ is the direction of transport, $j$ is the polarization, $\theta_1$ and $\phi_1$ are the azimuthal and elevation angles of the flux on side 1 approaching side 2 relative to the direction of transport, $v_1$ is the transmission coefficient, $f_1$ is the carrier group velocity on side 1, $f_0$ is the equilibrium distribution of particles on side 1, and $k$ is the wavevector. In order to consider only flux approaching the inter-
face, integration is performed over half of the Brillouin zone and the absolute value of the group velocity, $v_1$, is taken. The phonon equilibrium distribution, $f_0$, is given by the Bose–Einstein distribution, $f_0 = 1/(\exp(h\omega(k)/k_B T) - 1)$. Assuming diffusive scattering, the directional dependance of Eq. 1 collapses and the expression for phonon flux across the interface from side 1 to side 2 becomes

$$q_{1 \rightarrow 2} = \frac{1}{8\pi^2} \sum_{j, k_j, k_z} \int_{k_{j1z1}}^{k_{j2z2}} h_{BD}(k_{j1}) v_{1}^{\text{inc}} \left| v_{1}(k_{j1}) \right| f_0 d\mathbf{k}_{j1} d\mathbf{k}_{z1}$$

This expression can be further simplified by assuming the materials in question can be described by an isotropic phonon dispersion. This yields

$$q_{1 \rightarrow 2} = \frac{1}{8\pi^2} \sum_{j} h_{BD}(k_{j1}) v_{1}^{\text{inc}} \left| v_{1}(k_{j1}) \right| f_0 d\mathbf{k}_{j1}$$

Under the diffusive assumption, the phonon transmission from side 1 to side 2 must relate to the phonon transmission from side 2 to side 1 via the expression $\zeta^{-1} = 1 - \zeta^{-1}$. Hence, through the application of detailed balance, $q_{2 \rightarrow 1}^{\text{inc}} = q_{1 \rightarrow 2}^{\text{inc}}$, it is possible to solve for $\zeta^{-1}$ explicitly. However, the formulation of the transmission coeffi-
cient is largely dependent on the assumptions invoked when applying detailed balance [36]. The transmission coefficient will be given explicit attention and specifically formulated for an isotropic solid-graphite interface in the next section.

The relationship between the phonon flux traversing an interface from side 1 to side 2 and $h_{BD}$ can be established through a modified form of Fourier’s law and noting that

$$q_{1 \rightarrow 2} = h_{BD} \Delta T_{1 \rightarrow 2} \Rightarrow h_{BD} = \frac{\partial q_{1 \rightarrow 2}}{\partial \Delta T_{1 \rightarrow 2}}$$

where $\Delta T_{1 \rightarrow 2}$ is the temperature drop across the interface. It is im-
portant to note that, in the purely diffusive regime, the phonon transmission probability is predicted as 50% in the limit of the same material on either side of the interface. Although this has previously been ascribed to an incorrect physical limit [10], this is in fact a correct description assuming the most rigorous definition of diffusive scattering of particles (a scattering particle at a diffuse interface has equal probability of scattering in all available directions) [38]. That is, given an interface between two identical mate-
rials and assuming that phonons scattering at a perhaps imaginary interface will scatter diffusively, then phonons will have an equal probability of scattering in all directions (forward and backward) and therefore the transmission probability of the incident phonon flux will be 50%. With this in mind, $h_{BD}$ is given by
It is important to remember that, for all intents and purposes, the transmission coefficient has already been formulated at this point in the derivation of the DMM. As a result, it is critical that any restrictions or allowances regarding the range of participating phonons established during the application of detailed balance and the formulation of the transmission coefficient must be upheld here as well.

2.2 Application to Solid-Graphite Interfaces. When considering transport across a solid-graphite interface it is important to recognize the extreme anisotropy of graphite. This extreme anisotropy results in very complicated phonon dispersion relationships and is evident when examining the thermal conductivity, where $a$-axis (in the basal plane) and $c$-axis (perpendicular to the basal plane) values differ by 3–4 orders of magnitude [39,40]. In addition to the anisotropy of graphite, the large difference in phonon cutoff frequencies, or vibrational mismatch, between most solids and graphite suggests that inelastic phonon scattering may provide an additional channel of energy transport across a solid-graphite interface [15,19,41]. Recently, a model was developed by Duda et al. [29] that accounts for inelastic scattering at interfaces where one material comprising the interface is characterized by high elastic anisotropy, such as graphite. Inelastic scattering is taken into account through a higher-harmonic approach outlined by Hopkins [42] and makes use of simplifying assumptions which are valid at elevated temperatures relative to the saturation temperature of vibrational modes in one direction.

Despite the complicated nature of the phonon dispersion relationships of graphite, an effective Debye density of states can be used to describe bulk graphite at temperatures above cryogenic [28,40]. This is made possible by the weak interlayer vibrational coupling in graphite, which can be described as a van der Waals type interaction and is associated with low-frequency vibrations. Dispersion diagrams of graphite show that acoustic interlayer vibrations exist at frequencies below 3 THz, 1 to 2 orders of magnitude below the longitudinal and transverse cutoff frequencies within the basal plane [18]. Additionally, studies examining both CNTs and graphite have indicated that interlayer acoustic modes saturate at temperatures above 50 K [14,43].

Developing the effective density of states for predictions of $h_{BD}$, one can consider first a single monolayer of graphite, described by a two-dimensional Debye density of states. Scaling this density of states by $N$, or the number of two-dimensional sub-systems per unit length, generates an effective density of states for the graphite system. The density of states for bulk graphite (or, likewise, multilayer graphene stacks) thus becomes

$$D_{\text{eff}}(\omega, v_{a,j}) = N \omega \frac{1}{2\pi v_{a,j}^2} = \frac{\omega}{2\pi v_{a,j}^2} \frac{1}{d},$$

where $d$ is the interlayer spacing and $v_{a,j}$ is the polarization-specific Debye phonon group velocity in the basal plane [28,29]. Therefore, realizing that under the Debye assumption the relationship between $\nu$, $\omega$, and $k$ simplifies such that

$$\nu = \frac{\partial \omega}{\partial k} = \frac{\omega}{k}$$

the thermal flux in graphite perpendicular to the interface reduces from the form of Eq. 2 to

$$q_{b,j} = \pi \int_{\omega_{a,j}} h \nu v_{\text{eff}} D_{\text{eff}}(\omega, v_{a,j}) f d\omega.$$ 

The subscript $z$ denotes the orientation of the graphite relative to the interface and can take on two values, either $a$ (basal planes perpendicular to the interface, transport along the basal planes), or $c$ (basal planes parallel to the interface, transport perpendicular to the planes). Note that the density of states and cutoff frequency do not depend on the graphite orientation since the vibrational modes are assumed only to exist in the basal plane. Still, the propagation velocity does depend on the orientation. Three modes of vibration are still assumed within graphite (one longitudinal, two degenerate transverse). Phonon group velocities in the basal plane ($a$-axis) are taken as $v_{a,j} = 23,600$ m/s and $v_{c,j} = 15,900$ m/s [40]. A polarization-averaged group velocity is taken perpendicular to the planes, $v_c = 2,157$ m/s [44]. Assuming a planar lattice point density in graphite as $N_0 = 1.9 \times 10^{19}$ m$^{-2}$, the $a$-axis cutoff frequency is defined as $\omega_{a,j} = v_{a,j}/\sqrt{4\pi N_0}$ [45]. Values for density, $\rho_1$, and velocities, $v_{1,j}$ are taken from Swartz and Pohl [30].

Following the theory from previous work developed to account for multiple phonon diffusive scattering events at solid–solid interfaces [42], Eq. 9 is reformulated to explicitly describe multi-phonon processes by utilizing a transmission coefficient that is separated into components. Here the analysis is limited to four and fewer phonon processes, as the contributions of higher order processes do not significantly contribute to $h_{BD}$ at lower temperatures (below the Debye temperature of one or both materials comprising the interface) [42]. This approach enables the specific contributions to the transmission coefficient from the two-phonon elastic processes to be distinguished from contributions from the inelastic three- and four-phonon processes, yielding

$$h_{BD}^{1-g,z} = \frac{1}{4} \sum_{j} \int_{\omega_{a,j}} h \nu v_{\text{eff}} D_{1}(\omega, v_{a,j}) \frac{1}{\omega} \frac{1}{\omega} f^{1-g,z}(\omega) d\omega, \quad (9)$$

where the film properties are denoted by the sub- or superscript “1”. In this work, a three-dimensional isotropic Debye density of states is used to describe the film, and $\omega_{a,j} = v_{a,j}/\sqrt{4\pi N_0}$ [45]. Values for density, $\rho_1$, and velocities, $v_{1,j}$ are taken from Swartz and Pohl [30].

While this treatment of inelastic scattering may not be exact, it serves as a good firstapproximation to the relative contribution of inelastic processes to thermal transport at interfaces. The elastic transmission coefficient (assuming two-phonon scattering) is defined as outlined by [36] so that detailed balance on each phonon frequency yields

$$h_{BD}^{1-g,z} = \frac{1}{4} \sum_{j} \int_{\omega_{a,j}} h \nu v_{\text{eff}} D_{1}(\omega, v_{a,j}) \frac{1}{\omega} \frac{1}{\omega} f^{1-g,z}(\omega) \frac{1}{\omega} f^{1-g,z}(\omega) d\omega, \quad (10)$$

which assuming completely diffusive scattering ($f^{1-g,z} = 1 - \zeta^{(2,z)}(\omega)$), yields a two-phonon transmission coefficient of

$$\zeta^{(2,j)} = \frac{v_{a,j} 1}{v_{a,j} 1} = \frac{v_{a,j}}{v_{a,j} 1} \frac{1}{d}. \quad (12)$$

In the development of Eq. 12, the transmission coefficient is calculated on a per frequency, as well as per polarization, basis, which assumes not only completely elastic processes but also, in contrast to typical approaches of diffuse scattering, that a phonon of mode $j$ can only couple with another phonon of the same mode. This ensures phonon number conservation for both the elastic as well as the higher order processes [40]. Although this abandons
the pure definition of diffuse scattering (phonon loses memory and can scatter to any mode), in the Debye approximation, this assumption does not make a substantial difference in the overall result [28].

The determination of the three-phonon inelastic transmission probability begins with a balance similar to Eq. 11, only assuming two-phonons of energy \( \omega \) in the film will couple with a phonon of energy \( 2\omega \) in the substrate, so that the balance equation becomes

\[
2\hbar v_{13}(\omega , v_{13}) f(\omega) \xi_{(3)j}^{1-g_{z}} (1 - \xi_{(3)j}^{1-g_{z}}) = \hbar(2\omega) v_{24} D_{(2\omega)}(2\omega, v_{24}) J(2\omega) (1 - \xi_{(3)j}^{1-g_{z}}) \xi_{(2)j}^{1-g_{z}},
\]

when \( 0 < \omega \leq \frac{1}{2} \omega_{Dj} \) and

\[
2\hbar v_{13}(\omega , v_{13}) f(\omega) \xi_{(3)j}^{1-g_{z}} (1 - \xi_{(2)j}^{1-g_{z}}) = \hbar(2\omega) v_{24} D_{(2\omega)}(2\omega, v_{24}) J(2\omega) \xi_{(3)j}^{1-g_{z}},
\]

when \( \frac{1}{2} \omega_{Dj} < \omega \leq \omega_{Dj} \), where \( f(2\omega) = [\exp(\hbar(2\omega)/k_{B}T) - 1]^{-1} \).

This gives a three-phonon transmission coefficient, defined as

\[
\xi_{(3)j}^{1-g_{z}} = \begin{cases} 
\frac{v_{24} f(2\omega)}{2\pi v_{24}} \frac{1}{\xi_{(3)j}^{1-g_{z}}} & 0 < \omega \leq \frac{1}{2} \omega_{Dj} \\
\frac{v_{24} f(2\omega)}{2\pi v_{24}} \frac{1}{\xi_{(2)j}^{1-g_{z}}} & \frac{1}{2} \omega_{Dj} < \omega \leq \omega_{Dj} 
\end{cases}
\]

The development of the four-phonon process follows in a similar fashion, but has been omitted from this work for the sake of brevity.

The predicted temperature-dependent contributions to \( h_{BD} \) at Au-graphite interfaces from the two-phonon elastic process as well as the three- and four-phonon inelastic processes, assuming heat transport is perpendicular to the graphite substrate (c-axis), are shown in Fig. 1. The total \( h_{BD} \) is the sum of the two-, three-, and four-phonon contributions. These results illustrate the fact that the contributions from inelastic processes become more significant as temperature increases. Table 1 lists the contributions of each process, as well as the total predicted for Au to c-axis graphite \( h_{BD} \) at 300 K. This model suggests that at room temperature, in excess of 40% of the heat conducted across the Au-graphite interface is through inelastic channels.

### 3 Measuring Thermal Boundary Conductance

In order to investigate the effect of interfacial structure and chemistry on \( h_{BD} \), three metal-on-graphite samples were prepared for experimental thermal characterization. The three samples consisted of thin Au films on 12 mm × 12 mm × 1 mm grade 1 highly-ordered pyrolytic graphite substrates (HOPG) from Structure Probe Incorporated. Gold was chosen over other possible metals in order to reduce the number of variables affecting thermal transport across the interface. Previous work has shown that Au does not wet HOPG or other carbon-based substrates. As a result, the Au-HOPG surface interaction is characterized by weak van der Waals adhesion [23,46,47]. Thus, this choice of material system eliminated the variability of bonding reported when more reactive metals (e.g., Ti [22]) are deposited on HOPG.

Prior to metal deposition, each substrate underwent a different surface pretreatment to influence the interfacial structure and chemistry. The first substrate was cleaned using the “scotch tape method” to remove the first few layers of graphene, and no other pretreatment or cleaning method was used. The second substrate was cleaned in the same manner and subsequently ion cleaned. A 3 cm ion source, located 14 cm from the substrate, with a beam voltage of 300 V was used to surface etch the substrate, for a total exposure time of 7 min. As a means of comparison, exposing a SiO$_2$ wafer to these conditions removes approximately 5–10 nm of material from the surface and creates a disordered surface. The third substrate was again cleaned in the same manner and was subsequently electron cleaned. The conditions of the electron cleaning were the same as the ion cleaning, however, the beam voltage was turned off. It is presumed the electron heating from both the cathode filament and the neutralizer filament (which sits outside/at the end of the ion source) helps to remove surface water from the substrate. After all surface pretreatments, 50 nm of Au was deposited on the HOPG surface by direct current sputtering. These three surface treatments should have a significant impact on the condition of the Au-HOPG interface, as it has been demonstrated that contaminants and defects can lead to increased interaction between metals and HOPG [21,22].

Thermal boundary conductance of each Au-HOPG interface was measured via TTR. Transient thermoreflectance [48–50] and its variations [51,52] are optical thermometry techniques that use pulsed laser systems to both heat and monitor the surface temperature of a metallic thin film. A schematic of the TTR system used in the Nanoscale Energy Transport Lab at the University of Virginia is shown in Fig. 2. The pulsed laser source was a Coherent Mira 900 oscillator pumped by ~28% output from a Coherent Verdi V18, producing pulses on the order of several nJ per pulse at a repetition rate of 76 MHz. The output from the Mira 900 was then seeded into a Coherent RegA 9000 amplifier pumped by the remaining 72% output from the Verdi V18. The amplifier increases the pulse energy from several nanojoule to several microjoule per pulse. The fundamental output of the amplifier was 1.55 eV at 250 kHz with ~160 fs pulse widths.

A Newport 600 mm linear delay stage was used to delay the probe for a total of 4 ns temporal delay, while maintaining less

| Table 1 Individual contributions of two-, three-, and four-phonon processes for Au to c-axis graphite thermal boundary conductance at 300 K (in MMWm$^{-2}$K$^{-1}$). |
|---|---|---|---|
| Two-phonon | Three-phonon | Four-phonon | Total |
| Au | 13.3 | 6.5 | 2.9 | 22.8 |

**Fig. 1 Individual contributions of two-, three-, and four-phonon processes for Au to c-axis graphite thermal boundary conductance**
than 2 μm of linear drift in the vertical and horizontal direction along the length of the stage. The pump beam was modulated using a Conoptics Electro-optic modulator at 125 kHz before being passed through a frequency doubling BBO crystal to improve signal-to-noise filtering. The pump and probe beam were focused down using objective lenses to a spot size of 236 μm ± 2 μm and 26 μm ± 0.6 μm, respectively. For the data taken in this study, the incident pump fluence was set to ~2 J/m².

Each of the prepared samples was thermally characterized via TTR at temperatures ranging from 78 to 400 K. In order to explicitly determine \( h_{\text{BD}} \), the measured data are fit to a 1D two-layer heat conduction model \([12]\) and \( h_{\text{BD}} \) is adjusted such that the square of the difference between the raw data and the thermal model is minimized. An inverse parabolic interpolation technique is used during fitting to reduce the number of iterations required for the system to converge. The data of each scan are individually fit and a single “measured” value of \( h_{\text{BD}} \) is determined per scan; these fit values are subsequently averaged.

The temperature-dependent \( h_{\text{BD}} \) data are presented in Fig. 3. Each point in the figure represents the average of the ten measured values at that particular temperature. Error bars represent the standard deviation of the best fit \( h_{\text{BD}} \) for the ten scans. As clearly evident in Fig. 3, different HOPG surface preparations drastically change the behavior of phonon transport across the Au-HOPG interface. The as-cleaved sample exhibited the highest values of \( h_{\text{BD}} \) across the entire temperature range, followed by the electron cleaned, and lastly, ion cleaned. The difference between measured \( h_{\text{BD}} \) for the as-cleaved and ion cleaned samples is in excess of 300%, demonstrating how greatly surface preparation, and hence, the physical aspects of the interface, can impact interfacial thermal transport.

![Fig. 2 Schematic of transient thermoreflectance setup at University of Virginia.](image1)

4 Theoretical and Experimental Comparison

In addition to the experimental data, Fig. 3 also includes the elastic and inelastic predictions of phononic thermal transport at the Au-HOPG interface. From comparison of the experimental data and the predictive modeling, several important features are prominent. First, the electron cleaned data demonstrate good agreement with the inelastic model. This can be explained in the sense that the electron cleaning effectively removes contaminants from the HOPG surface without inducing disorder. As a result, this interface nearly mimics the ideal interface assumed by models like the one presented above (it has been shown that freshly cleaved graphite in air has a surface roughness of less than 1 nm \([53]\)). As a result, the model can accurately capture the behavior of phonon transport across the Au-HOPG interface. The presence of contaminants on the surface of the as-cleaved sample should lead to increased reactivity between Au and HOPG \([21]\), suggesting increased adhesion strength, and hence, higher \( h_{\text{BD}} \) \([24]\). Lastly, the ion cleaned HOPG substrate should be highly disordered as a result of the heavy ion bombardment. As has been shown by Hopkins et al. \([13]\), increased atomic mixing and disorder at the interface has a detrimental effect on \( h_{\text{BD}} \). While these...
trends can be inferred with confidence, further structural characterization is still required.

Conclusions

Predictions of $h_{BD}$ utilizing the DMM vary for highly acoustically mismatched and anisotropic materials depending on the materials used and the assumptions made. For isotropic solid-graphite systems, a combination of reduced dimensionality, highly anisotropic thermal properties, large vibrational mismatch, and poor interfacial adhesion require the extension of the traditional DMM proposed by Swartz and Pohl [30]. The DMM is modified to account for the extreme anisotropy of the substrate by means of a modified effective density of states, treating the substrate as a system of weakly coupled two-dimensional Debye subsystems. The large vibrational mismatch between the solid-graphite systems allows for the possibility of additional thermal transport channels through inelastic phonon–phonon scattering processes, with increasing importance as temperature increases. To account for inelastic scattering, the anisotropic DMM is extended further to account for additional three- and four-phonon inelastic processes. To further consider the importance of interfacial structure and chemistry, experimental measurements of $h_{BD}$ on three Au-HOPG samples with different substrate surface preparations were taken using transient thermoreflectance over the range from 78 to 400 K. Comparisons were made between the experimental measurements and the modified DMM assuming both elastic and inelastic scattering. The theoretical model assuming inelastic scattering and the experimental data match very well for Au on an electron cleaned HOPG substrate, the sample most representative of the perfect theoretical interface. However, the model does not compare well to the results for Au on ion cleaned and as-cleaved HOPG samples. This is due to the one factor that has not yet been considered, the interfacial chemistry between the metallic film and the graphite substrate. Before a model that captures both the vibrational and structural properties of interfacial transport can be developed, a rigorous study of the effects of interfacial bonding and structural effects on $h_{BD}$ is required.
